Three possibilities to speed up the Hybrid Monte Carlo algorithm are investigated. Changing the step-size adaptively brings no practical gain. On the other hand, substantial improvements result from using an approximate Hamiltonian or a preconditioned action.

1. Introduction

The Hybrid Monte Carlo (HMC) algorithm[1] is now the standard method to simulate dynamical fermions. However the cost of the algorithm is substantial. It is therefore desirable to improve the efficiency of the HMC algorithm.

First, we examine the possibility of changing the step size adaptively[2,3]. Second, we implement the HMC algorithm with approximate Hamiltonians. Lastly, we precondition the fermionic action used in the HMC algorithm.

2. HMC with adaptive step size

The conventional HMC algorithm is performed with a fixed step size. One expects however that the molecular dynamics (MD) trajectory will bounce off the effective energy barrier represented by the minimum of the fermionic determinant. As it does, the curvature increases and so does the integration error. This effect should be more pronounced for smaller quark masses. Therefore one might expect, in that regime, benefits from varying the step size adaptively.

The naive way to adapt the step size consists in keeping the local error constant at each integration step. But care must be taken to preserve time-reversibility. Stoffer has constructed a time-reversible adaptive step size method which gave promising gains on the Kepler problem[4]. Here we implement this method for the HMC algorithm.

Call $T(\Delta t)$ a one-step integrator; $T(\Delta t) : (p, U) \longrightarrow (p', U')$. It maps momenta and link

variables (p, U) onto (p', U') . Now we define a symmetric error estimator,

$$E_S(p, U : \Delta t) = e(p, U : \Delta t) + e(p', U' : -\Delta t), \quad (1)$$

where $e(p, U : \Delta t)$ is a local error at (p, U) when the system is integrated by $T(\Delta t)$. If the integrator is reversible, eq.(1) is obviously symmetric under the exchange $(p, U, \Delta t) \longleftrightarrow (p', U', -\Delta t)$. The adaptive step size Δt is then determined by solving a symmetric error equation,

$$E_S(p, U : \Delta t) = \textit{tolerance} \quad (2)$$

The tolerance should be kept constant during the MD simulation. The adaptive step size determined by eq.(2) takes the same value at the reflected point $(-p', U')$. Therefore an integrator with the adaptive step size determined by eq.(2) is reversible. Taking for T the standard leapfrog integrator, we tested the above method for several quark masses, volumes and couplings[3]. We observed that the variance of the step size increases as κ increases, as expected. However, it decreases as the volume increases. Thus the gain over HMC with fixed step size turns out to be very small. The overhead to determine the adaptive step size by solving eq.(2) exceeds this gain.

3. HMC with approximate Hamiltonian

The leapfrog integrator with step size Δt has $O(\Delta t^3)$ errors, resulting in an energy violation ΔH , which reduces the Metropolis acceptance. Since such errors are present anyway, there is no need to keep for the molecular dynamics Hamiltonian H_{MD} the exact Hamiltonian H . An approximate Hamiltonian H_{MD} which introduces

*Talk presented by T. Takaishi at LATTICE96

errors of similar magnitude can be substituted at cheaper cost. The cost of the HMC algorithm is expressed by the cumulated cost of fermionic force evaluations per accepted trajectory:

$$C_t = \frac{N_D}{Acc \times \Delta t} \quad (3)$$

for trajectories of a certain fixed length, where N_D is the number of multiplications by the Dirac operator D at each step of size Δt . In the following, we consider two possibilities to decrease N_D and try to find the minimum cost C_t .

3.1. Chebyshev polynomial approximation to the Hamiltonian

Lüscher proposed to approximate the inverse of the fermion matrix D by a Chebyshev polynomial $P_n(D)$ of degree n with zeroes z_k :

$$D^{-1} \simeq P_n(D) = c_n \prod_{k=1}^n (D - z_k) \quad (4)$$

This approximation allows the construction of a local update algorithm with n auxiliary bosonic fields[5]. Here we use the same approximation for the inverse of the fermion matrix which appears in the molecular dynamics Hamiltonian:

$$\phi^\dagger (DD^\dagger)^{-1} \phi \rightarrow \phi^\dagger P_n(D)^\dagger P_n(D) \phi \quad (5)$$

This formulation does not require any linear solver. The fermionic force evaluation requires instead a predetermined $N_D = 2n$ multiplications by D . As n is reduced however, the approximation (3.1) increases the energy violation, which reduces the Metropolis acceptance. Fig.1(a) shows the efficiency $2/C_t$ vs. Δt . We find that the optimal step-size depends little on the degree n of the polynomial. For the optimal n , the work is reduced by about 4 over standard HMC.

3.2. Low accuracy stopping criterion

Usually, in the molecular dynamics steps, the linear system which gives the fermionic force is solved to high accuracy. The initial guess to the solution of this linear system can then be extrapolated from previous results without measurably spoiling time-reversibility. In this way, the number of iterations in the solver can be reduced by a factor ~ 2 [6]. On the other hand, it is also possible to reduce the accuracy in the solver, provided that the solution is time-reversible. This is

Figure 1. (a) Efficiency vs. step-size Δt for polynomials of various degree n . For the standard HMC, the number of iterations in the $BiCG\gamma_5$ solver was taken as n . The stopping accuracy was set to $\|r\| = 10^{-8}$, where $\|r\|$ is the residual norm. (b) Efficiency vs. residual norm. The trajectory length is $1(0.5)$ for a $4^4(8^4)$ lattice.

achieved simply by forfeiting the benefits of time extrapolation, and taking always the same initial guess for the solver. While this second approach is well-known, its benefits have not been studied to a comparable extent.

Here we systematically investigate the optimal accuracy, which minimizes the cost of HMC, by varying the stopping criterion in the solver. In this case, the actual form of the corresponding Hamiltonian H_{MD} can not be known. Fig.1(b) shows efficiency, acceptance and number of iterations. The number of iterations linearly decreases with the logarithm of the stopping criterion. On the other hand, the acceptance remains practically constant up to a certain stopping criterion and then rapidly decreases. We measure the efficiency by $Acc/\# \text{ of iterations}$. The figure clearly shows that a low accuracy stopping criterion ($\|r\|^2/\|r_0\|^2 \approx 10^{-5}$ and 10^{-6} on 4^4 and 8^4 lattices, respectively) is most efficient. However the gain over standard HMC ($\|r\|/\|r_0\| = 10^{-8}$) appears to decrease as the volume increases.

4. HMC with preconditioned action

The use of preconditioners is well-known for the solution of linear systems, like the one which gives the fermionic force F_f at each step. On the other hand, little attention has been paid to preconditioning

tioning the fermionic action itself. One exception is even-odd preconditioning:

$$S_f = \phi_e^\dagger (D_{ee}^\dagger D_{ee})^{-1} \phi_e \quad (6)$$

where

$$\det(1 - \kappa M) = \det(1 - \kappa^2 M_{eo} M_{oe}) \equiv \det(D_{ee}). \quad (7)$$

This formulation is widely used to reduce memory requirements and work per force evaluation. What has not been noticed is that the fermionic force from (6) is smaller than in the non-preconditioned case (see Fig.2), allowing for an increase in the step-size without loss of acceptance. This benefit stems from the better conditioning of D_{ee} (to order κ^2) than D (to order κ). This preconditioning can be pushed to higher order with virtually no overhead. Consider the partitioning of D_{ee} :

$$D_{ee} = 1 - (\kappa^2 M_{eo} M_{oe})_+ - (\kappa^2 M_{eo} M_{oe})_-, \quad (8)$$

where $+$ ($-$) stands for the lower(upper) triangular part. The lower(upper) triangular matrices L and $U = 1 - (\kappa^2 M_{eo} M_{oe})_\pm$ have determinant 1. The preconditioned matrix $L^{-1} D_{ee} U^{-1} = 1 + \mathcal{O}(\kappa^4)$ can then be substituted to D_{ee} in the fermionic action:

$$\begin{aligned} S_f &= \phi_e^\dagger [(L^{-1} D_{ee} U^{-1})^\dagger (L^{-1} D_{ee} U^{-1})]^{-1} \phi_e \\ &= \phi_e^\dagger (U D_{ee}^{-1} L) (L^\dagger D_{ee}^{-1} U^\dagger) \phi_e. \end{aligned} \quad (9)$$

The corresponding fermionic force is obtained as:

$$\frac{\partial S_f}{\partial A_\mu} = \eta_e^\dagger \frac{\partial D_{ee}}{\partial A_\mu} x_e + \phi_e^\dagger \frac{\partial U}{\partial A_\mu} x_e + \eta_e^\dagger \frac{\partial L}{\partial A_\mu} L^\dagger \eta_e + h.c. \quad (10)$$

with $\eta_e = D_{ee}^{-1} U^\dagger \phi_e$; $x_e = D_{ee}^{-1} L L^\dagger \eta_e$. Since no inverse of L or U appears in this formulation, the overhead in the force calculation is negligible. As shown in Fig.2, the fermionic force is reduced by a factor ~ 2 as κ_{LU} changes from 0 (standard even-odd) to its optimum slightly below κ . It becomes much smaller than the gauge force. A Sexton-Weingarten integration scheme [7] then allows to take very large fermionic step-sizes.

This *ILU* preconditioner can be implemented to higher order in κ , with some programming headache. The same idea can also be used for staggered fermions.

Figure 2. RMS force for various actions.

We tested *ILU* preconditioning eq.(9) on a $16^3 \times 32$ lattice, at parameters studied by the SESAM collaboration ($\beta = 5.6, \kappa = 0.1575$) [8]. We could increase the fermionic step-size from 0.01 (SESAM) to 0.05 while maintaining a 66% acceptance. A more extended, though still preliminary test was conducted on an 8^4 lattice at $\beta = 5.6, \kappa = 0.1585$. These parameters were chosen in [9] to compare HMC with the multiboson method, very near criticality. *ILU* preconditioning allowed us to increase the fermionic step-size from 0.075 to 0.12. At the same time, we used a low-accuracy stopping criterion $\|r\|/\|r_0\| = 10^{-3}$ during the trajectory, reducing the number of matrix multiplications per step from $\sim 2 \times 159$ to $\sim 2 \times 66$. The autocorrelation time of the plaquette seems unaffected by preconditioning.

If these preliminary indications are confirmed, the prospect is to improve the efficiency of HMC by a factor $\mathcal{O}(5)$.
